INTRODUCTION

In preparation for the field study to determine the adequacy of hearing protection for use with the M198, 155mm howitzer, a special purpose, multichannel audiometer was developed. The development of the audiometer was initiated in December 1976 in preparation for a "quick fix" for the M198 blast overpressure problem. Between 1976 and 1980, there were numerous delays in executing the "quick fix." During this time, the original audiometer was constructed and the system underwent several modifications which altered its final capabilities. This report documents the development of the audiometer and its calibration.

The design characteristics of the special purpose audiometer were determined primarily by the operational requirement to measure auditory thresholds (audiograms) before and after exposure to weapons noise in a field setting. These audiograms had to be determined quickly, accurately, and reliably with minimally trained volunteers.

A modified Von Bekesy tracking procedure (Von Bekesy, 1947) was selected for this purpose. The procedure was based on testing discrete frequencies for a fixed length of time. This would permit the calculation of time between the noise exposure and the testing of each frequency. The system had to have a wide dynamic range to be capable of determining thresholds which were 20 to 30 dB better than normal and thresholds which were temporarily elevated well above normal. The original design requirement for six people to be tested simultaneously was later reduced to four people. In addition, noise excluding headphones were required to permit audiometric testing under adverse environmental noise conditions.

With these design characteristics established, a search for a commercially available unit was undertaken. None could be found which met all requirements. In-house development then was initiated utilizing available audio components to the maximum extent possible. The requirement for six channels, fixed time of testing each frequency, and use by minimally-trained individuals suggested that a microprocessor control system with digitally controlled attenuators and data collection capability would be most suitable. This also established the possibility of automatic data transfers to desk top calculators for rapid data analysis. This latter capability was added after the initial system fabrication. No satisfactory noise-excluding headphones could be identified which would yield acceptable noise reduction at the subject's ear. Therefore, standard audiometric headphones were mounted in good hearing protective earmuffs to meet this requirement.

An attempt was made during the development process to maintain maximum flexibility of the microprocessor control over the hardware components of the system. This flexibility was accomplished by insuring the system's ability to be modified by changing software. Various audiometric and analysis procedures could be implemented without a requirement for direct engineering support.

Once the system was fabricated, it was subjected to a series of comparison tests in the laboratory and in the USAARL Mobile Audiometric Test Trailer to determine its performance as compared to a high quality clinical audiometer. Since the headphones could not be calibrated by standard methods (due to the nonstandard mounting), a biological calibration factor was developed and validated by these comparison tests.

METHODS AND MATERIALS

A block diagram of the multichannel microprocessor controlled audiometer is shown in Figure 1. The system is comprised of two parts; (1) stimulus generation, and (2) control and data processing. Each channel of the audiometer includes a programmable attenuator, step attenuator, 1-watt power amplifier, earphones, and response switch. These items are shown on the

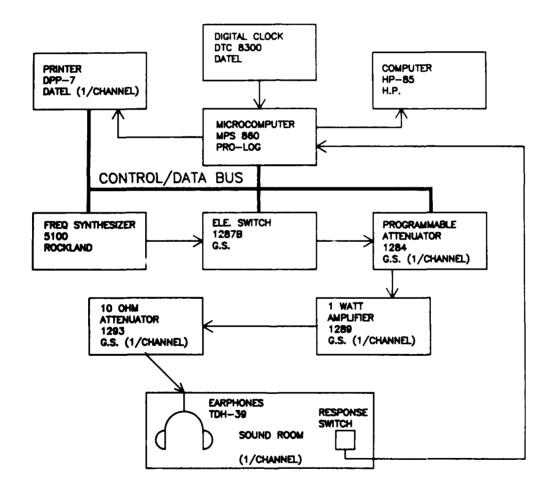

FIGURE 1. Block Diagram of Multichannel, Microprocessor Controlled Audiometer (MCA).

block diagram for a single channel. The remainder of the components are common to all channels. The system utilizes a hex keyboard for the operator to enter data or control the audiometer. The audiometer is designed for 6-channel operation; however, the USAARL mobile audiometric trailer limits the system to four channels.

The frequency synthesizer is controlled by the microprocessor to produce the stimuli for the audiometer. The frequency, order of frequency, and number of frequencies are stored in memory and may be modified. The frequencies presently used range from 500 Hz to 8 kHz with a presentation order of 2K, 4K, 6K, 3K, 8K, 2K, 1K, and 500 Hz. The test signal produced by the synthesizer is input to the electronic switch where it is pulsed with a microprocessor-controlled period of 350 ms. The electronic switch is adjusted to provide a 25 ms rise and fall time gate on the stimuli to eliminate audible clicks. The output of the electronic switch is input to the programmable attenuator of each channel.

Each programmable attenuator is capable of controlling the stimulus level over a range of 128 dB in 0.5 dB increments. An increment of 2 dB was considered adequate for the threshold determination accuracy required for weapons field studies. The attenuator is a binary weighted system where the 2ⁿ result is the attenuation in dB. A 6-bit up/down counter, with the stages of the counter attached to corresponding stages of the attenuator, is used to control the attenuator setting. The up/down control of the counter is directly related to the subject response switch. If the subject hears the tone and presses the switch, then the up/down control is set for up count and when the clock pulse is received from the microprocessor the attenuator increases its attenuation by 2 dB. The up/down counter may be preset to any value by the microprocessor. The state of the up/down counter is capable of being read by the microprocessor.

After output from the programmable attenuator, the signal is amplified by the 1-watt amplifier, then passes through the 10 ohm step attenuator to the Telephonics* TDH-49 earphones which are worn by the test subject. The step attenuator may be adjusted over a range of 100 dB in 5 dB increments. In this application the step attenuator is used to decrease the system noise level at the earphones, and also to provide the experimenter with a means of checking listener reliability. Figure 2 shows the completely assembled audiometer rack, mounted and ready for use.

The threshold determination procedure uses the tracking method (Von Bekesy, 1947). The threshold determination for a particular frequency consists of four segments. The first segment provides the listener with two pulses of the stimulus at a level approximately 40 dB above hearing threshold. This alerts the listener that a test trial is beginning and provides him with a cue as to the sound of the stimulus. The second segment is the beginning of

^{*}See Appendix A

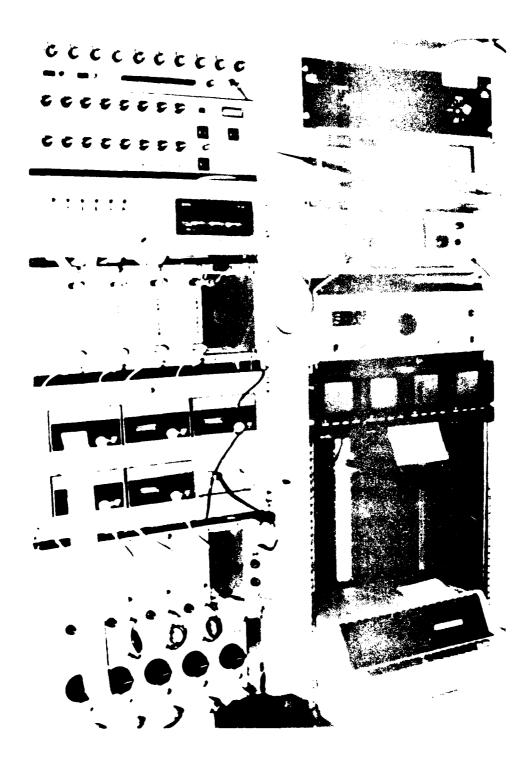

FIGURE 2. Photograph of Microprocessor and alled Audiometer System.

the threshold tracking task. The level of the stimulus begins at approximately 10 dB Hearing Threshold Level (HTL) and is controlled by the listener torough the hand switch. This segment presents 16 tone pulses (approximately 6.6 sec) to allow the listener to converge to his threshold before data are collected. The third segment, consisting of 48 pulses (16.8 sec), involves the collection of threshold data. Each time the response switch state changes during the tracking process the attenuator value is read and stored by the microprocessor. The fourth segment is the development of the mean attenuator value which is translated into HTL and printed. This process is completed for all frequencies and for both the left and right ears.

Data are output to either the Datel* printer or the Hewlett-Packand* HP-85 computer. If the printer is used, prior to each test frequency the subject's identification number, the date, the test frequency, and the start time for that test frequency are printed. During the test each time the microprocessor detects a change of state for the subjects response switch, the value of the programmable attenuator (corrected for HTL) is printed. After the test frequency is completed, the total number of switch state changes and the mean attenuator value (corrected for HTL) are printed. If the HP-85 is used, the programmable attenuator value at switch state change time is displayed on the CRT at the end of the test frequency. When the subject has completed the entire audiogram, all data may be stored on cassette tape for later analysis.

The headsets used in this application were designed and built using "off-the-shelf" components of proven quality (Figure 3). The transducers were matched pairs of TDH-49 earphones purchased specifically for this project. They were enclosed in earmuffs obtained through the federal supply system (National Stock Number 4240-00-759-3290). Installation of the earphones was accomplished by drilling 1/4" holes through the walls of the earcups. Rubber grommets were inserted and Belden* 8411 coaxial cable was passed through the grommets to the TDH-49 earphones. The opposite enus of the cable were terminated with a standard stereo phone jack. The cables were approximately 6 feet long to allow mobility for the earphone wearer.

The original foam material from inside the earcups was removed and used as a pattern to cut new inserts to go in the cups. The new inserts were made from 3/4" thick open cell foam polyester with a specific density of 2.25 · 0.5 lbs/cu ft.

The earphones were centered in the earcups and held in place with specially-built retainers made of Plexiglas. The retainers were backed with a very thin sheet of polyester foam to prevent direct contact with the earphones. The earphones and retainers were covered with a 3/8" sheet of open cell polyester foam. The original ear seals were used, as were the suspension systems and head cushions.

ASSESSED RECEIVED RECEIVED RECEIVED RECEIVED

Right and left earphones were connected to the stereo phone jack in a predetermined fashion and labeled by placing tape on the right cup to ensure that the subjects always placed the right and left earphones on the correct ear. Figure 4 shows the assembled headset unit.

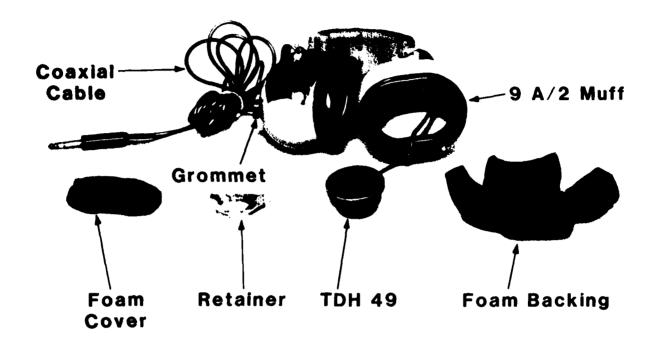

FIGURE 3. Components of the Audiometric Headsets.

Acoustic calibration of the headsets was accomplished using a Bruel and Kjaer (B&K)* type 4153 artificial ear fitted with a flat plate adapter. A B&K type 4134 microphone was used with the coupler and a type 2619 preamplifier connected to a model 227 multiplexer amplifier. The sound pressure levels were read on a B&K Model 2606 measuring amplifier with external filter type 1618. The measurement system was calibrated with a B&K type 4220 piston phone prior to the calibration of the headsets. The headphone acoustic calibration was accomplished by setting the audiometer to provide an output of 67.5 dB SPL at 1000 Hz measured at the right earphone. The output at all test frequencies was measured at both earphones with this attenuator setting held constant.

Since the nonstandard mountings of the headphones precluded calibration by standard methods, a biological calibration was performed. This was done

FIGURE 4. Assembled Audiometric Headset.

CHANGE TO SOUND THE SOUND THE SOUND THE SOUND TO SOUND TO SOUND THE SOUND TH

in two phases. First, the threshold was measured on a group of four listeners (Group 1) using a Grason-Stadler* 1701 audiometer and the new audiometer. These listeners were not screened for normal hearing (some did have a high frequency hearing loss.) The GS-1701 audiometer was calibrated to the manufacturer's specifications in accordance with American National Standards Institute (ANSI) S3.6 (1969).

Audiograms were repeated five times for each listener on each system. The new audiometer thresholds were in values of attenuation. This first phase was

used to derive a conversion table which was incorporated in the derectors of program to convert these threshold attenuation values to estimates of dearing Threshold Level (HTL). The second phase of biological calibration involved the comparison of HTLs measured on the Grason-Stadler 1701 and on the new audiometer. This comparison was accomplished in the USAARL mobile audiometric trailer.

Ten listeners (Group 2) produced three audiograms each on each audiometer. These listeners were selected for normal hearing in accordance with ANSI S3.19 (1974). Three of these listeners produced six additional audiograms for a total of nine audiograms on each audiometer. Table 1 contains the ambient noise levels in the laboratory audiometric room and in the mobile audiometric facility used for the biological calibrations.

RESULTS AND DISCUSSION

Table 2 contains the estimated Sound Pressure Levels (SPL) at HTL of zero, as derived from the initial biological calibration and the flat plate calibration. For comparison, the SPL values at audiometric zero provided by Grason-Stadler (1971) are included also. The sound pressure levels of the MCA headphones agree with the reference levels of the Grason-Stadler 1701 except at 8.0 kHz.

*Source: Grason-Stadler, a GR Company. 1971. 1701 Audiometer Instruction Manual. Concord, Massachusetts: Grason-Stadler Company, Inc.

Table 3 contains a summary of the second phase of biological calibration. The mean and standard deviation of threshold obtained on the Grason-Stadler 1701 and the new audiometer are shown for the ten Group 2 listeners tested three times each. These results give an indication of the accuracy of the MCA compared to the standard audiometer. With the exception of 6.0 kHz in the right ear, the agreement is within the tolerances specified in ANSI S3.6 (1969).

The reliability of the MCA can be estimated from measures of variability of the individual audiograms. Because of individual differences in threshold between listeners, the results of the nine repeated audiograms on the three Group 2 listeners and the five repeated audiograms of the four Group 1 listeners were used to compute standard deviations and range of thresholds for each listener on each audiometer. These results are presented in Table 4. These standard deviations and ranges give an indication of the relative reliability of the two audiometers. As can be seen, for most listeners at most frequencies there is little difference between the reliability of the two audiometers. However, at some frequencies (especially the higher ones), the MCA is clearly more reliable than the clinical audiometer. This is probably a result of the difficulty of obtaining a consistent earphone placement with the clinical auidometer and standard headphones. The superior reliability of the MCA system is particularly important for threshold shift studies since individual audiograms must be used without retesting or averaging to improve reliability.
